Abstract: This paper extends the literature by looking at the contribution of non parity variables after extracting the impact of parity variables on exchange rates of Australia and the Asia Pacific countries. Exchange rates are examined using high- and low-frequency multi-country panel time series data for a group of trade related nations in the Asia Pacific. Our findings suggest that exchange rate is affected by growth rate, and trade and capital flows. Other less significant variables include sovereign debt, balance of payments, money supply, and trade openness. It also confirms that interest rate has a significant effect on exchange rates while price effect is not significant in short-run regressions. These key findings are robust across different time intervals, thus revealing new findings on the exchange rate dynamics consistent with theory.

Keywords: Exchange rates, foreign debt and reserves, growth, monetary and fiscal policy, parity theorems, trade and capital flows

JEL classification: F31, F32, G15

1. Introduction

This paper aims to present findings on exchange rate behaviour by including new theoretical precepts supported by empirically verified factors as well as other principal theories that are suggested to investigate exchange rate determination in a trade related multi-country context using new research tools. One particular unexplored factor in international finance is the role of capital flows in recent decades in the determination of exchange rates (see Harvey 2001). There is a need to go beyond the traditional price and interest parity factors employed to study exchange rates of small to medium sized economies. Secondly, after much effort at studying bilateral (two-country) exchange rate determination, which has yet to provide consistent findings in the vast literature of this ilk, a new approach using multi-country framework and an improved research design is needed to understand exchange rate equilibrium. This paper attempts to do this.

[#] This paper is based on a study that was supported by a funding to the first author by the University of Technology MARA. The study was completed while both authors were at Monash University, which also supported this research by providing access to the database and funding for research support to the second author. We thank the anonymous reviewer and the editor of the Journal for useful comments while retaining responsibility for remaining errors.

Researchers have expressed increasing frustration over their failure to explain exchange rate movements (Dornbusch 1987a; b; MacDonald and Taylor 1992). With rapid growth in trade and capital flows across national boundaries, newer key factors are noticed as affecting the value of foreign currency (Harvey 2001). These factors are many and include current account deterioration, excessive foreign debt accumulation, capital flows, foreign currency reserves and fiscal imbalances. Additional factors that are viewed and verified in some studies as affecting exchange rate are economic growth, exchange rate regimes and uncontrolled monetary expansion.

This study extends the exchange rate literature by looking at the contributions of non parity variables after extracting the impact of parity variables as a first step: for this we used a two-step regression popularised in the 1990s, and widely used in studies in finance. The findings provide an improved understanding of the dynamics of how exchange rates are determined in a trade related multi-country context by using control factors beyond the traditional parity conditions. We have included countries in a trade related group if the bulk of the trade of that country is with the other countries in the grouping.¹ We have also provided a single country study of Australia.

For the multi-country Asia Pacific region as a whole, we find that the interest rate parity holds well and this study concludes that increases in nominal interest rates lead to downward movements in exchange rates, that is, exchange rate improves as Fisher effect kicks in. A faster economic growth rate in the region significantly facilitates strengthening of currency values. In addition, monetary expansions are positively related to domestic exchange rates and this might be a reflection of faster growth rates driving monetary expansion. From separate findings for Australia, as a comparison with a developed country in the region, economic growth rate is the major determinant of exchange rate movements. Accumulation of international reserves and the domestic monetary stance are also important factors in the shorter term.

The remainder of this paper is divided into five sections. The next section contains a brief overview of current literature which assisted in identifying fundamentals relevant to this study. Section 3 illustrates the methodology adopted, followed by a discussion of the significant findings and robustness of testing in Sections 4 and 5 respectively. Section 6 concludes the paper.

2. Literature on Exchange Rate Determination

The currency exchange market is the world's largest market in terms of daily trading volume—in excess of USD 2.3 trillion in 2007—no comparison to even the world's combined bond or stock markets.² The imports and exports of goods and services, coupled with international capital flows, could account for only a part of this huge currency transaction. Speculative trade in currency forms a major part of this transaction. The primary function of the foreign exchange market is to facilitate international trade and investment as well as permit transfers of purchasing power denominated in one currency to another.

¹ We grouped 54 countries into 5 trade-related groupings; the Asia Pacific countries is one of the five groupings thus formed.

² The *Economist*. April, 2001. Forex is 50 times larger by volume than the equity market as stated by *Euromoney.com*. Resnick, Bruce G. *Business Horizons*, Nov/Dec 89, Vol 32, Issue 6 and updated by others.

The two-parity theorems of exchange rates include the Purchasing Power Parity (PPP) of Cassel (1918) as well as the Interest Rate Parity (IRP) of Fisher (1930). These theorems have been extensively tested by renowned scholars all over the world. Interest in currency behaviour has been rekindled because of the incompleteness of our knowledge on exchange rate determination in the face of periodic currency crises, and by the availability of newer statistical tools, as well as the accumulation of data over long periods.

2.1 Purchasing Power Parity

PPP has been viewed by many as a basis for international comparison of income and expenditure, an equilibrium condition and an efficient arbitrage condition in goods as well as a theory of exchange rate determination. PPP established a common ground for cross-country comparisons by linking currencies of different countries to price levels—or more precisely, price differences across countries—as the base. The underlying theory is based on a simple goods market arbitrage argument; ignoring tariffs, transportation costs, and assuming common goods consumed that should ensure identical prices across countries, under the law of one price. While this notion appears simple enough, specifying comparative prices between two countries in the short run is difficult. This has led to the majority of empirical literature failing to verify that PPP holds.³

The relative version of PPP suggests that if a country's inflation rate is relatively higher than its trading partners, that country will find its currency value falling in proportion to its relative price level increases. The exchange rate E adjusts by k as a function of P^d domestic prices and P^f foreign prices.

$$E = k \left(\frac{P^d}{P^f} \right) \quad (1)$$

Taking log on both sides, the following allows for a testable proposition:

$$\ln E_{jt} = a_j + b_j \ln \left(\frac{P_t^d}{P_t^f} \right)_j + \mu_{jt} \quad (2)$$

where j represents country, t represents time period, P represents prices, d domestic and f foreign.

In order to allow for constant price differential between baskets, the bulk of empirical tests focused on testing relative consumption-based PPP which requires that changes in the relative price levels between countries be offset by changes in their bilateral exchange rates.

Evidence on short run PPP holding is lacking giving the impression that the theory of PPP had failed to hold.⁴ The apparent lack of evidence even under most of the current

³ Empirical work that has led to conflicting empirical findings for PPP includes MacDonald (1993), Rogoff (1996), Edison *et al.* (1997), Cheng (1999) and Bayoumi and MacDonald (1999). They have all found no clear evidence, or at best, very weak relationship between inflation and exchange rates.

⁴ Henry and Olekaln's (2002) study on Australia found little evidence for long run equilibrium between exchange rate and prices. In a similar view, Adler and Lehman (1983) found that the deviations from PPP follow a random walk without reverting to PPP for 43 countries.

floating regimes provides researchers the opportunity to revisit this theme. It was this same urge that led to the development of the sticky price model of Dornbusch (1976). In the last two decades, despite a number of studies using unit root tests, researchers have failed to reject the null hypothesis of the random walk.⁵ Froot and Rogoff (1994) concluded that PPP is not a short-run relationship: this is the basis of our research design as to why we used different time intervals. Prices do not offset exchange rate swings on a monthly or even annual basis. Frankel and Rose (1996a) examined PPP using a panel data set of 150 countries over forty-five years and confirmed that PPP holds and their estimate implied a half-life of PPP deviations of four years, that is, the parity is long term.

2.2 Interest Rate Parity

Interest rate parity (IRP) is the law of one price in the asset market for securities.⁶ In theory, the foreign exchange market should be in equilibrium when deposits of all currencies offer the same rate of return. A rise in interest rates will attract more investment into the country resulting in an appreciation of the currency in the short run and exchange rates falling in the long run to restore equilibrium. According to the uncovered interest rate parity, the ratio of changes in exchange rate E , within a time period t , is a function of domestic interest rate i^d , and foreign interest rate i^f .

$$\frac{E_{t+1}}{E_t} = \left(\frac{1 + i_t^d}{1 + i_t^f} \right) \quad (3)$$

While PPP implies that exchange rates will adjust to changes in inflation differentials, International Fisher Effect (IFE) implies that relative interest rate differentials will give rise to similar final results in exchange rates. The ability of exchange rate markets to anticipate interest differentials is supported by several empirical studies that indicate the long run tendency for these differentials to offset exchange rate changes.⁷

2.3 Non Parity Variables

Some researchers point out that over the last two decades, other variables have emerged to correlate with exchange rate movements.⁸ These variables could shed fresh light, and assist in identifying other-than-parity explanations for understanding exchange rate behaviour. Despite the fact that parity explanations have gained a centre stage up until

⁵ MacDonald and Ricci (2001), Kuo and Mikkola (2001), Lothian and Taylor (2000), Mark and Sul (2001), Schnabl and Baur (2002) found considerable evidence for long-run relation and concluded that fundamentals play a significant role in determining exchange rates.

⁶ The interest rate theory was first developed by Keynes (1923) and Fisher (1930) through the introduction of Fisher effect for domestic interest rate theory.

⁷ Studies that provide evidence include Mark (1995), Chortareas and Driver (2001), Chinn and Meredith (2002), Hoffman and MacDonald (2003) which found measures of long run expected changes in exchange rates highly correlated with interest rate differentials.

⁸ Frankel and Rose (1996b) on current account and government budget deficits; Calvo *et al.* (1994) on capital flows, inflation and current account deficits; and Aizenman and Marion (2002) on reserve and credibility; and many others.

about the 1980s for exchange rate behaviour research, recent years have witnessed interest in other explanations, given the conflicting empirical evidence on parity theories. The theoretical evidence and empirical studies on these non-parity variables are systematically examined here.

2.3.1 Current and Capital Account Deterioration

Studies on the financial crises in Latin America and East Asia have been motivated by an interest in the roles of banking and balance of payments. The trade and capital balances are known to be most sensitive to exchange rate changes. For countries affected by the 1997/98 Asian financial crisis, the reversal of capital flows, and current account deficits (together with high foreign debt) have been suggested as common factors surrounding that crisis.⁹ Karfakis and Kim (1995) using Australian exchange rate data found that an unexpected current account deficit is associated with a depreciation of exchange rates and a rise in interest rates. Evidence that current account deficits reduce domestic wealth and may thus lead to overshooting of the exchange rates resulting in a fall in the real value of the currency have being reported by Obstfeld and Rogoff (1995a; b), Engel and Flood (1985), and Dornbusch and Fisher (1980). There has also been a surge in international capital flows into developing countries in the recent decades.¹⁰ These capital flows affect domestic output, real exchange rates, capital and current account balances for years thereafter.¹¹

Portfolio investment has also increased in recent years due to greater access to capital markets via newer regulations, reduced capital controls and the overall globalisation of financial services.¹² Calvo *et al.* (2003) blamed the fall of Argentina's currency programme on their country's vulnerability to sudden stops in capital flows. A recent study by Kim (2000) on four countries that faced currency crises found that reversal of capital flows as well as current account deficits are significantly related to currency crises in these countries.¹³ Rivera-Batiz and Rivera-Batiz (2001) concluded that explosion in capital flows resulted in higher interest rates and depreciation of exchange rates in the long run.

⁹ It is documented that the recent currency crises were due to vast changes in these variables, including that of Kim (2000).

¹⁰ Gross foreign direct investment as a percentage of GDP increased more than 100 per cent for Korea, the Philippines and Indonesia for the period 1990-2001. Net private capital flows into six developing regions in the world totalled USD167.976 billion in 2001. Source: *2003 World Development Indicators*, database, World Bank, 13 April 2003.

¹¹ Studies on capital flows that affect output, exchange rates and balance of payments include Kim (2000) and Calvo and Reinhart (1999).

¹² Portfolio investment inflows have increased from RM19,346 million in 1991 to a peak of RM238,454 million in 1994 for Malaysia. Source: Bank Negara Malaysia and Department of Statistics, Malaysia. Portfolio investment averaged USD102 billion for 1995-96 and USD26 billion for 1997-2000 according to World Economic Outlook, 2003, IMF.

¹³ Using annual data for 21 OECD countries, Krol (1996) found that capital flows have a significant effect on current accounts as well as exchange rates and this is reinforced by Kim (2000).

2.3.2 Loss of International Reserves and Excessive Foreign Currency Debt

The amount of international reserves held by the central authority is another factor affecting exchange rate determination.¹⁴ The use of reserves as a means to defend a country's currency provides credibility to the value of the currency. This suggests that reserves and the type of currency exchange regime (in this case, managed float as a camouflage for trade advantage) are likely to affect exchange rates.¹⁵

Calvo *et al.* (1994) showed that an increase in capital inflows increased total reserves and real exchange rates of Latin American countries. Marini and Piersanti's (2003) study covering Asian countries found that a rise in current and expected future budget deficits generated appreciation in exchange rates and a de-cumulation of external assets, resulting in a currency crisis when foreign reserves fell to a critical level. Hsiao and Hsiao (2001) found a unidirectional causality from short-term external debt/international reserves ratio to exchange rates in Korea. As in the case of Martinez (1999) on Mexico, Frankel and Rose (1996b) studied a large group of developing countries and found that the level of debt, foreign direct investment, foreign interest rates, foreign reserves and growth rates affect exchange rates significantly.

2.3.3 Trade Openness, Slow Growth, Fiscal Imbalances, and Excessive Monetary Expansion

Globalisation has resulted in domestic financial markets being slowly more integrated with international financial markets (Edwards and Khan 1985; Ariff 1996). Open economies facing capital flows, competitive interest rates and trade competition from others must lead to a defined relationship between openness and the rate of growth in some countries.¹⁶ As in the study of Karras (1999), Papell and Theodoridis (1998) who studied openness, exchange rates and prices, found stronger PPP evidence for countries with less exchange rate volatility, and shorter distance from other countries but not for countries with greater openness to trade.

Among the many models found in the literature to explain long-term deviations in PPP, the most popular one is from Balassa (1964) and Samuelson (1964). Both argued that technological progress has historically been faster in the traded goods sector than in non traded goods sector and therefore traded goods' productivity bias is more obvious in higher income countries. Froot and Rogoff (1994) and Rogoff (1999) further showed that rapidly growing countries would tend to experience exchange rate appreciation relative to their slower growing partners when technological changes happen more often in the trading goods sector as a result of intense international competition. The studies of Canzoneri *et al.* (1999), Chinn (2000), Duval (2002), and Cheung *et al.* (2003) have also added to this argument.

¹⁴ Korea's usable reserves fell from USD28 billion to a mere USD6 billion when their currency went on a free fall in December 1997: Aizerman and Marion (2002). Brazil's reserves fell from USD75 billion to less than half of that before the currency collapsed in 1998: Dornbusch and Fisher (2003).

¹⁵ Total external debt for six developing regions in the world according to World Bank classification amounted to USD2,332,621 million for 2001. Source: 2003 *World Development Indicators*, World Bank.

¹⁶ Karras and Song (1996) investigated 24 OECD countries for thirty years and found a positive relationship between output volatility, economy's trade openness and exchange rate flexibility.

MacDonald and Wojcik's (2003) study on EU accession countries found that productivity, as well as private and government consumption, significantly affected exchange rate behaviour. In contrast with Edwards and Savastano (1999), Bailey *et al.* (2001) found that increased labour productivity in the US resulted in current account deficits that are financed by large capital inflows, which appreciated the dollar exchange rates.

2.3.4 Exchange Rate Regimes

Since the breakdown of the fixed Bretton Woods system, exchange volatility has drastically increased to levels that are beyond the explanation of fundamentals.¹⁷ Grilli and Kaminsky (1991) concluded that real exchange rate behaviour changes substantially across historical periods but not necessarily across exchange rate regimes. Calvo and Reinhart (2002) examined thirty-nine countries around the world and found that moderate to large exchange rate fluctuations are very rare in managed float systems. Other studies that found similar results include Hasan and Wallace (1996), Moosa and Al-Loughani (2003) and Edwards (2002) who explained that super-fixed regimes were highly inflexible and inhibited adjustment process.

Hence there is literature support for checking the roles of many of these non parity factors in exchange rate determination.

3. Data, Methodology and Summary Statistics

3.1 Data

The data used relate to exchange rates between individual countries, and the United States (US) dollar (IFS line rf) as the foreign unit as observed at the end of observation periods.¹⁸ Quarterly bilateral exchange rates for Australia as well as nine other Asia Pacific countries are from 1974:4 to 2006:1. The *International Financial Statistics* (IFS) CD-ROM is the major source for these data. Price variables include CPI (IFS line 64) and PPI (IFS line 63) of individual countries; T-Bill and Money market rates (IFS line 60) are used to arrive at the interest differentials between countries. Changes in exchange rates, prices and interest differentials are calculated using natural logarithm.

The non parity current and capital flow variables include: trade balance (Trade) from imports and exports of goods, and current account balance (Cur); balance of payments (BOP) from overall balance; capital flows from both inflows and outflows of foreign direct investment (FDI) and portfolio investments (PT); and total reserves (TR) as well as foreign

¹⁷ Reviewing the US experience with flexible exchange rates, Dornbusch (1987b) found that changes in exchange rates in the last fifteen years are inconsistent with any explanation in theory and may not be related to fundamentals.

¹⁸ These exchange rate quotations can be expressed in either a unit of foreign currency (direct quote) or a local unit expressed in foreign equivalent (indirect quote). A direct exchange rate quotation gives the home currency price in terms of foreign currency whereas the indirect quote gives the one unit home currency equivalent in foreign currency. They are actually the reciprocal of each other. In order to avoid confusion, direct quotations are used, as is the practice in the literature, in this study unless stated otherwise.

debt (FD). Monetary expansion data is broader money¹⁹ (M2) which includes both money and quasi-money. Growth rate (PROD) is measured by change in Gross Domestic Product (GDP) per capita. The set of dummy variables includes exchange regimes which are grouped into three categories: free-float, exchange band/managed, and fixed regime.²⁰ Trade openness is measured by total trade (TTrade), that is, the sum of total imports and exports, as a proportion of GDP: this is used to form trade related groupings. Incomplete data are sourced from Datastream, World Bank as well as individual country's Central Banks and Statistics Departments. The independent variables are categorised into parity and non parity variables.²¹ A summary of variable definitions and their expected signs are found in Table 1.

The sample in this study includes Australia as an individual country and a selection of nine countries in the Asia Pacific region: Australia, Indonesia, Japan, Korea, Malaysia, New Zealand, the Philippines, Singapore and Thailand. The developed nations include Australia, Japan, New Zealand and Singapore and the rest are emerging economies with relatively high growth rates. The reason behind the choice of these nine countries is the high level of inter-trade between these countries in the same geographical region as shown in Table 2 and the availability of information with regard to these nations. We included these countries as each of the countries has a majority trade relation, that is, import and exports to other countries in the grouping is well above 50 per cent of total trade. We present this as the trade relatedness for selected countries to be included in a regional grouping (and thus we had five such groups made of 54 countries across the world, although this paper is on Asian Pacific grouping only). For related data, see Table 2: for example, Hong Kong has the bulk of its trade with the chosen group.

3.2 Methodology

The regression analysis tests the price and interest parity theorems and then includes other non parity fundamentals with appropriate tests to check the robustness and validity of results. The one-step ordinary least squares model has its limitations and hence a two-step regression is used to explain the unexplained effects captured in the residuals from the first regression using parity variables. The paper by Ball *et al.* (1980) popularised this procedure of extracting theory from suggested variables in the first step regression, and then taking the residual to further test the proposition. This procedure of first running a regression, and then using the residuals from the first regression as a dependent variable on further independent variables is thus followed. We followed this procedure as it is well established in studies on finance. This overcomes the problem of estimating the parity relations which have significant pair-wise correlations with non parity variables. The stepwise parsimonious regression approach using the well established AIC statistics allows an examination of each independent variable's contribution to the model, which will be useful in selecting a narrower

¹⁹ IFS defines money as the sum of currency outside deposit money banks and demand deposits, and quasi money as the sum of time, savings and foreign currency deposits of resident sector.

²⁰ Exchange regimes are according to Reinhart and Rogoff (2002).

²¹ In order to minimise multicollinearity effects, all parity variables were transformed as first difference and specified in the models as natural logarithm. Further investigation of the variables indicates no significant correlation among the independent variables using VIF tests.

Table 1: Summary of variables and definitions

No.	Variable	Definition	Expected sign
1.	InER	Log difference of Exchange Rate over time periods	
2.	InP	Log difference of Prices over time periods	+
3.	InI	Log difference of Interest Rate over time periods	+
4.	Trade/GDP	Trade Balance / Gross Domestic Product (GDP)	-
5.	Cur/GDP	Current balance / GDP	-
6.	BOP/GDP	Balance of Payment / GDP	-
7.	TRes/M	Total Reserve / Total Import	-
8.	FD/GDP	Foreign Debt / GDP	+
9.	InFDI/GDP	Inflows of Foreign Direct Investment / GDP	-
10.	OutFDI/GDP	Outflows of Foreign Direct Investment / GDP	-
11.	InPt/GDP	Inflows of Portfolio Investment / GDP	-
12.	OutPt/GDP	Outflows of Portfolio Investment / GDP	-
13.	Bdgt/GDP	Budget Deficit or Surplus /GDP	-
14.	TMy/GDP	Total Money (M2) / GDP	+
15.	Prody	Gross Domestic Product / Total Population	-
16.	TTrade/GDP	Total Exports and Imports / GDP	-
17.	Regime	Exchange Regime	+/-

Table 2: Proportion of trade between countries in the Asia Pacific region

Country	ASEAN	Japan	EU & UK	US	Korea	China	Hong Kong and Taiwan	Australia /New Zealand
Australia	14%	19%	12%	10%	8%	7%	4%	7%
Indonesia	14%	21%		13%	7%	5%	4%	5%
Japan	6%			30%	7%	10%	12%	5%
Korea		10%		20%		15%	6%	19%
Malaysia	25%	11%		21%	5%	7%	5%	7%
New Zealand		12%	10%	16%	5%	5%		20%
Philippines	12%	15%	10%	26%	4%	7%	12%	2%
Singapore	25%	7%	6%	15%	4%	6%	15%	3%
Thailand	15%	15%		20%	12%	5%	5%	9%

set of variables. The parity and non parity models include different tests of the price and interest parities individually as well as jointly in a multi-country framework.

3.2.1 Combined Price and Interest Parity Test

Investigating both price and interest parities should yield results that explain the extent to which parity hypotheses could explain changes in exchange rates:

$$\ln\left(\frac{E_{t+1}}{E_t}\right)_{jt} = \alpha'_{0j} + \alpha'_{1j} \ln\left(\frac{P}{P^*}\right)_{jt} + \beta'_{1j} \ln\left(\frac{1+i}{1+i^*}\right)_{jt} + e_{jt} \quad (4)$$

3.2.2 Non Parity Models

Exchange rates are also dependent, as argued in this paper, on changes in non parity variables especially in the short run. This section describes the tests aimed at estimating the individual effect such variables have on exchange rates. These variables will also be tested together, first in a general model, and subsequently eliminating uncorrelated variables by using the Akaike Information Criterion (AIC) that will result in a stepwise approach.

Step 1:

$$\text{Parity:} \quad \ln\left(\frac{E_{t+1}}{E_t}\right)_{jt} = \alpha'_{0j} + \alpha'_{1j} \ln\left(\frac{P}{P^*}\right)_{jt} + \beta'_{1j} \ln\left(\frac{1+i}{1+i^*}\right)_{jt} + \gamma_{jt} \quad (5)$$

Step 2:

Non Parity:

$$\begin{aligned} \gamma_{jt} = & a'_{0j} + b'_{1j} (\text{Trade} / \text{GDP})_{jt} + b'_{2j} (\text{Cur} / \text{GDP})_{jt} + b'_{3j} (\text{BOP} / \text{GDP})_{jt} + \\ & b'_{4j} (\text{InFDI} / \text{GDP})_{jt} + \\ & b'_{5j} (\text{OtFDI} / \text{GDP})_{jt} + b'_{6j} (\text{InPt} / \text{GDP})_{jt} + b'_{7j} (\text{OtPt} / \text{GDP})_{jt} + b'_{8j} (\text{FD} / \text{GDP})_{jt} + \\ & b'_{9j} (\text{T Res} / \text{Im})_{jt} + b'_{10j} (\text{Prody})_{jt} + b'_{11j} (\text{Bdgt} / \text{GDP})_{jt} + \\ & b'_{12j} (\text{TTrade} / \text{GDP})_{jt} + b'_{13j} (\text{TMy} / \text{GDP})_{jt} + b'_{14j} (\text{Re gime})_{jt} + v_{ij} \end{aligned} \quad (6)$$

where the dependent variable takes the residual value from the first regression. The first regression includes the effect of the parity relations, and the residual as the dependent variable for the second regression contains the potential effects from non parity relations. Thus, this two-step regression popularised by Ball *et al.* (1980) may be applied to investigate the parity and non parity relations both in time series – as depicted in the above – or in cross-sectional tests.

Most researchers use monthly or annual interval data to test parity theorems. Given the price stickiness and the evidence of long-run equilibrium on price parity, there is a need to test the relations using longer intervals of data. Therefore, we tested the regression by increasing the interval period and observing the variables across one, two, three and further years so that the tests may be conducted over a longer interval data to detect the impact of variables which have long-run impacts beyond one or more years. Thus, a 2-year window means that the variables are observed over a two-year period, and so forth.

Common problems faced in cross-sectional and time series analysis are non normality of variables, non stationarity of time series data, multicollinearity among criterion factors, autocorrelation and heteroscedasticity. The descriptive statistics of the variables are given in Appendix 1. Although not shown in the appendix, the variables were found to be normally distributed, given the transformation. The impact of multicollinearity is to reduce any single

independent variable's predictive power by the extent to which it is associated with the other independent variables. It can be detected using Variance Inflation Factor (VIF) that shows how the variance of an estimator is inflated by the presence of multicollinearity (Hair *et al.* 1998).²² Variables with larger VIF values or low tolerance level are excluded: alternatively, highly collinear variables may be joined in some transformation of the series. Our VIF statistics show that multicollinearity is not present in the regression: see footnote 21 and Appendix 2. As may be verified, the VIF statistics are below the critical values, thus indicating that multicollinearity is not likely to affect the test statistics in the regression.

The normality of all the variables will be tested to ensure multivariate normality and this is further ensured by specifying the variables in natural logarithms while stationarity of the series will be tested and confirmed by Augmented Dickey-Fuller (ADF) unit root test and the Kwiatkowski, Phillips, Schmidt and Shin (KPSS) Test (see Appendix 3 and also footnote 21). The presence of heteroscedasticity is detected by White's test using Eviews software: though the test results are not reported here, we used appropriate corrections for the heteroscedasticity problem. To ensure that the assumption of constant variance is not violated, the heteroscedasticity and autocorrelation problems were tested and corrected using the Eviews process.

4. Findings

This section reports the quarterly as well as other interval results on both Australia and the Asia Pacific region. Since the exchange rate used in this model is against the foreign currency, a negative coefficient corresponds to an increase in the value of domestic currency and a positive coefficient indicates otherwise.

4.1 Short Term - Australia

From the quarterly results in Table 3, it is important to note that higher growth rate stands out clearly as the major determinant of exchange rates in Australia. This model, however, cannot find any indication of the purchasing power and interest parity in the short term which is consistent with the current empirical literature. Although statistically insignificant, the coefficient for trade has the right sign where an increase in trade leads to appreciation of the domestic currency. The coefficient for foreign debt is insignificant and in the opposite direction to the theoretical prediction: it cannot be explained. Capital and portfolio flows are insignificant but the short-run coefficients have the expected signs. It appears that for a developed country, capital and debt flows do not have a significant impact on its economy and therefore its exchange rates. That is the short-run story. Total reserves have an insignificant coefficient though the sign is consistent with theoretical expectation that an increase in reserves raises the confidence level others have on its currency value. The government's fiscal budget is insignificant but of the correct sign. This reflects that the fiscal budget condition does not drive the value of the currency. Monetary policy of the government is also not significant (t -statistic of 1.22) where excessive monetary expansion leads to deterioration of currency value. The total trade or trade openness coefficient is

²² These test results are shown in this paper in Appendix 2 on more than the variables included in this study: we did the tests with the methods described in this paper and other methods used to study the other four regions.

insignificant and the relationship is negative. The sign reflects that openness to trade resulted in huge imports that send the currency value falling. The *F*-probability of 0.000 shows that the model is statistically significant and that growth rate is the major driving force behind exchange rate movements. The adjusted R-squared of 0.873 also indicates that more than 80 per cent of the movement in exchange rates can be explained by this model.

4.2 Short Term – Asia Pacific Region

For the region as a whole (Table 3), interest and price parities do not hold in the short run as these are statistically insignificant in the short run, consistent with current literature. The coefficient for growth rate of -57.30 is highly statistically significant with a major effect on exchange rates as well as in the expected direction. Improvement in the balance of payments leads to an increase in the value of domestic currency in the region; nonetheless it is only marginally significant with a *t*-statistic of -1.77. It is most interesting to note that domestic monetary expansion is significant and directly related to the value of the currency. This is not consistent with the monetarists' model and might be a reflection of rapid growth of the region driving monetary expansion. The coefficient for foreign debt of 0.162 is statistically significant and shows that an increase in sovereign debt negatively impacts domestic exchange rates. The government's fiscal budget is another significant determinant of exchange rates for Asia Pacific countries in the short term where improvement in the budget balance improves the exchange rate performance too.

The capital, portfolio flows, and monetary regime are generally insignificant and this shows that short run quarterly changes in these variables do not have a strong impact on exchange rates. Total trade of the region is also significant but is inversely related to exchange rates. This might be explained by the large amount of imports absorbed into the region when these countries accumulated wealth through rapid growth which is supported by huge exports too. Thus trade openness allows these countries to import more productive technologies and it facilitates sustaining of higher and continuous growth. With adjusted R-squared of 0.738 for a region of nine countries, the model can explain more than 70 per cent of changes in exchange rates.

4.2.1 Short Term - Parsimonious Model

The parsimonious model in Table 4 indicates similar findings for the region and confirms the significance of growth rates and others on exchange rates. These results are more reliable. Sensitivity analysis of the tests was conducted with no substantial differences to the reported results. The parsimonious model indicates that the coefficients for the five major factors for the region of Asia Pacific countries are namely (i) growth rates, (ii) balance of payment, (iii) budget balance, (iv) foreign debt accumulation, and (v) total money. They continue to be statistically significant which is consistent with theories and some studies. The other variables are not significant and some of them have incorrect signs.

4.3 Longer Term - Australia

The longer term results are shown in Table 5 as a comparison from short to longer periods of time. It is crucial to note that purchasing power parity is achieved in two years for Australia, which is not only statistically significant (*t*-statistic is 3.71) but of correct sign. Sample sizes are too small to allow reliable use of parity fundamentals to predict changes in exchange rates, even when these fundamentals do determine exchange rates. A further study with longer time series in the future should obtain more significant results.

Without doubt, growth rate is the major determinant of exchange rates in Australia from the results obtained here for quarterly as well as all subsequent time periods. Fiscal stance is also an important longer term variable, as fiscal expansion is inversely associated with the

movement of exchange rates and is statistically significant in both one- and three- yearly regressions. Monetary expansion is becoming more important in the longer term and the results correspond to theory; it is indirectly related to exchange rates. It is important to note that exchange rate appreciation of a certain magnitude always becomes more worrisome if coupled with excessive monetary expansion.

The coefficients of foreign debt of 2.219 and 1.951 are significant and of the correct direction for one- and two-year intervals. This shows that in the longer term, persistent accumulation of foreign debt decreases the value of the currency when investors lose confidence in the ability of the country to repay its foreign debt. Moreover, high foreign debt leads to further deterioration of the economy if accompanied by high world interest rates.

Non parity variables which are marginally significant in affecting exchange rates in the shorter time period also include inflow of foreign direct and portfolio investments which are positively related to exchange rates in the one yearly interval. This shows that in the longer term, inflows of investment increase the value of the Australian currency and likewise for accumulation of balance in the current account. The *R*-squared for all the period intervals are above 80 per cent and this shows that the models can explain a large portion of exchange rate movements. In summary, the key driving force behind the Australian currency is still growth rates in the domestic economy. Other variables that affect exchange rates include inflow of foreign direct and portfolio investments, foreign debt accumulation, total trade, and monetary and fiscal stance of the government.

4.3.1 Parsimonious Model

The results from a parsimonious model given in Table 6 clearly show that growth rate is the major determinant of exchange rates in Australia. It is interesting to note that accumulation

of reserves and portfolio outflows are also significant determinants for one- and two-yearly intervals, respectively.

4.4 Longer Term - Asia Pacific Region

Consistent with the theoretical position, interest parity theory is consistently holding in the region as a whole as it is statistically significant in all the yearly intervals as shown in Table 7. Price parity, however, is not explained in the model here. It might be, since these countries are relatively new with data of only about thirty years, a longer time period and a longer series of data once available in the future, would enable more significant results to be determined using our interval method to control the sticky price.

The coefficient for growth rates, interest rates and total money are statistically significant in four-year intervals and are the major forces behind exchange rates in the region. The growth of countries in this region helps to explain the increase in currency value throughout the thirty years of the study. The balance of payments is only a shorter term variable in determining exchange rates in the region as accumulation of the balance is reflected in an improvement in exchange rates as predicted. Monetary expansion in the region is positively related to exchange rates and trade openness is negatively related to exchange rates as explained in the earlier section.

Although significant only in the shorter term, the coefficient on foreign debt of 0.262 at four-year intervals is in the expected direction in the longer term. Other capital and portfolio flows, current account, and trade flows are insignificant in affecting exchange rates which is surprising because it is believed that they are the major reasons for the financial crisis in the region in 1997. This might be due to the insufficient length of time series available from these countries when some of them only started recording these flows in the late nineties.

The parsimonious result in Table 8 reinforces the findings from Table 7. Overall, the adjusted *R*-squared are all above 75 per cent which shows that the models can explain a

high proportion of changes in exchange rate in the region. On top of that, the *F*-probabilities for the models are very significant.

5. Testing for Robustness

This paper undertook robustness tests to reaffirm the results. We first removed statistically insignificant variables from the model to form the parsimonious model. The results were found to be robust to the removal of these variables, with all explanatory variables and significance of coefficients persisting. Further, using stepwise approach reconfirms the existing results, as seen above.

We also removed relatively highly correlated variables from the model (despite the VIF tests) and re-ran the analysis. The results largely persisted. The outflows of capital and portfolio figures are generally not significant anyway and when they are removed, the number of observations increases and adjusted *R*-squared also increases. Overall, the *F*-statistics of the models improved and the models are statistically significant.

6. Conclusion

This study reports new findings, if accepted, may extend the existing currency literature by considering the extent to which both parity and non parity variables influence exchange rates in Australia and also in a region of nine closely trading countries in the Asia Pacific. We find that of the non parity variables for Australia, three have extensive explanatory power in the models investigated in this paper: (1) growth rates, (2) foreign debt and (3) fiscal expansion. Collectively, these variables explain about 80 per cent of the changes in exchange rates in Australia. The parity variables, on the other hand, are generally statistically insignificant. Two other non parity variables which are marginal and therefore not significant, include (4) monetary expansion and (5) inflow of foreign capital.

The major driving forces behind exchange rates in the Asia Pacific region as a whole are (1) interest rates, (2) growth rates and (3) monetary expansion. Interest parity (4) is consistently holding in the region for all intervals of time periods. Price parity (5) however, needs further extension of data and tests in a future study due to insufficient data for these relatively new countries: as mentioned earlier, we could not extend the tests beyond 4-year intervals; this is too short to reveal the price parity equilibrium given sticky prices. Other minor non parity variables that appear to be statistically borne out are identified: balance of payments (6), government's fiscal balance and trade openness (7), as these factors are not always significant in all regressions. The explanatory power of the models is also large.

It is important to note that different countries face different sets of parity and non-parity variables which are significant in driving their exchange rates. The results for parity and non parity variables are robust to alternative specifications of the model. We believe the tests developed in this study have led to improved results, and help identify new variables that are related to exchange rates while the puzzle of short-term versus long-term behaviour is made obvious by applying different interval periods. It is to be noted that the use of different interval periods, beyond the monthly and quarterly intervals used by most researchers, enabled us to bring in the impact of long-cycle sticky price effect. Finally, this study ventured to include factors suggested by theories and empirical reports to identify non parity variables, which appear to be very significant contributors to determination of the exchange rate.

Critical values for ADF tests at 10, 5 and 1 per cent levels of significance are respectively, -2.59, -2.90 and -3.53 with a constant and -3.17, -3.48 and -4.09 with a constant and a deterministic trend. Critical values for KPSS tests at 10, 5 and 1 per cent levels of significance are respectively, 0.35, 0.46 and 0.74 with a constant and 0.12, 0.15 and 0.22 with a constant and a linear trend.

Note: For the ADF tests, the unit root null is rejected if the value of the DF *t*-statistics is less than the critical value. For the KPSS tests, the null of stationarity is rejected if the value of the KPSS statistic is greater than the critical value. *, ** and *** denote statistical significance at 10, 5 and 1 per cent levels. The critical values for the ADF tests are from MacKinnon (1991).
